## ABSTRACT

A nulling five-hole pressure probe was used to complete a flowfield survey behind a close-coupled canard and wing model set at 22 degrees angle of attack. The canard and wing were both low-aspect-ratio, highly-swept, delta planforms with rounded leading edges. The model was set at the condition of maximum lift enhancement of the canard/wing configuration over a corresponding wing-alone configuration, based on previous force measurements. For comparison, the pressure measurements were made with the canard on and with the canard off. From the pressure measurements, flowfield velocity-vector, velocity-streamline and total-pressure-coefficient contours were plotted. These plots showed the dramatic effect of the canard vortex on the wing flowfield. The location and interaction of the canard and wing leading-edge vortices were analyzed. Large-scale reattachment of previously reversed flow over the wing was noted, as well as the re-establishment and strengthening of the wing leading-edge vortex.

## **ACKNOWLEDGEMENTS**

I offer my sincere gratitude to Professor Richard M. Howard. His untiring dedication and hard work are the reason this thesis was completed. I wish all the best of luck to a man so deserving.

I also wish to thank Mr. Don Meeks and Mr. Ron Ramaker for their outstanding and timely technical support during this study.

Lastly, but most importantly, I would like to thank my neglected family, especially my wife Laurie, for their patience and understanding.

## **I. INTRODUCTION**

### **A. SUPERMANEUVERABILITY**

In modern aerial combat, the ability of an aircraft to maneuver into the post-stall regime for short periods of time is crucial to its survivability. Current fighter aircraft, such as the Israel Aircraft Industries Lavi, SAAB Gripen or European Fighter Aircraft (EFA), employ a close-coupled canard to allow for continued maneuvering where conventional aircraft may have departed from controlled flight. This increase in maneuverability results from the favorable interaction of vortices over a delta wing. Double-delta wings or leading-edge strakes, such as those on the F/A-18 or F-16, have been used to enhance the lift in the same way. However, until recently, only the SAAB Viggen had been successful at using a canard to maintain lift at high angles of attack.

### **B. CLOSE-COUPLED CANARD**

The advantages of a close-coupled canard have been known since the 1960's. It was found by Behrbohm [Ref. 1] that the combination of a close-coupled canard and delta-wing, of small aspect ratios, has significant advantages over a conventional delta-wing or wing/horizontal-tail configured aircraft. Both  $C_{Lmax}$  and the angle of attack for  $C_{Lmax}$  are increased by the addition of a delta-canard to a delta-wing. During the 1970's, an experiment was performed by Lacey [Ref. 2] to determine the correct canard geometry and location for maximum lift enhancement. As a result of Lacey's work, Behrbohm's conclusions concerning the use of a delta-canard with a delta-wing were confirmed. It was found that locating such a canard above, rather than coplanar with, the main wing produced the most favorable vortex interaction. In the 1980's canard research continued. Work by Er-El [Ref. 3], Stoll and Koenig [Ref. 4] and Calarese [Ref. 5] provided insight into

canard/wing vortex interaction. However, most of their work was done at low to moderate angles of attack with little or no canard deflection.

At the Naval Postgraduate School, a series of experiments has been conducted to compare a close-coupled canard model, designed in accordance with Lacey's work [Ref. 2], to a wing-alone configuration. The first tests, conducted by Kersh [Ref 6], were to determine the forces on the model up to  $50^\circ$  angle of attack. During these tests, the canard was deflected between plus and minus  $25^\circ$  to determine which canard incidence angle would produced the maximum lift at a given model angle of attack. It was determined that the maximum lift enhancement of the canard/wing configuration over the wing-alone configuration occurred at  $22^\circ$  model angle of attack with the canard set at a positive  $7^\circ$  incidence. At this angle of attack, the first stall (loss of lift) occurred on the wing for the wing-alone case; the canard vortex seemed to provide a reattaching mechanism. Reference 6 is a complete discussion of Kersh's work.

### **C. THESIS OBJECTIVE**

This thesis was the second in the series of tests conducted for canard/wing lift enhancement. The model was set for maximum lift enhancement conditions as described above. Wake surveys were then conducted using a nulling five-hole pressure probe. The objective was to gain quantitative data concerning the total pressure and velocity profiles at three crossplane locations, while the model was operating at  $22^\circ$  angle of attack, with and without the canard. By this approach the effect of the canard leading-edge vortex on the main wing leading-edge vortex would be further investigated. From the pressure data, velocity-vector plots and total-pressure contours were generated for a comparison between the wing-alone and canard/wing configurations. Such a comparison served to help reveal the enhancement mechanism at an angle of attack beyond those investigated previously.

## II. BACKGROUND

### A. VORTEX GENERATION

The dominant characteristic of flow over a highly-swept delta wing is the generation of a strong leading-edge vortex as shown in Figure 1. These vortices are the result of separated flow at medium to high angles of attack. As opposed to the chaotic, separated flow associated with stall, these vortices are stable, coherent sources of high energy and generate areas of low static pressure resulting in localized regions of enhanced lift at the leading edge.

**Figure 1. Flowfield Over the Top of a Delta Wing**

The strongest vortices result from planforms with sharp, highly-swept ( $>50^\circ$ ) leading edges. The sharp leading edge promotes the leading-edge separation necessary for vortex generation. However, the combination of large sweep and a sharp leading-edge produces a large planform with a low  $(L/D)_{\max}$  and a shallow lift-curve slope. The net result is poor range and endurance, high approach speeds and large deck space requirements. These characteristics are extremely undesirable traits for a carrier-based aircraft. [Ref. 2]

The requirement for carrier suitability, therefore, dictates the design of an aircraft with rounded, moderately-swept leading edges. When such a planform maneuvers to high angles of attack the vortices produced are less coherent and of lower energy. Therefore, some mechanism is needed to energize or induce these vortices to remain coherent at high angles of attack, without the added penalty of poor cruise performance.

## B. CANARD CHARACTERISTICS

Canards are separated into two broad categories: long-coupled or close-coupled (see Figure 2).

**Figure 2. Canard Categories [Ref. 2]**

Long-coupled canards are of the type used primarily as a control surface rather than as a lifting surface. Examples of this type are found on almost all missiles and on some aircraft, such as the XB-70, the Concorde and the X-31 experimental aircraft. A close-coupled canard may provide a significant portion of the aircraft total lift in addition to being a control surface. The aircraft listed at the beginning of the introduction are examples of close-coupled designs.

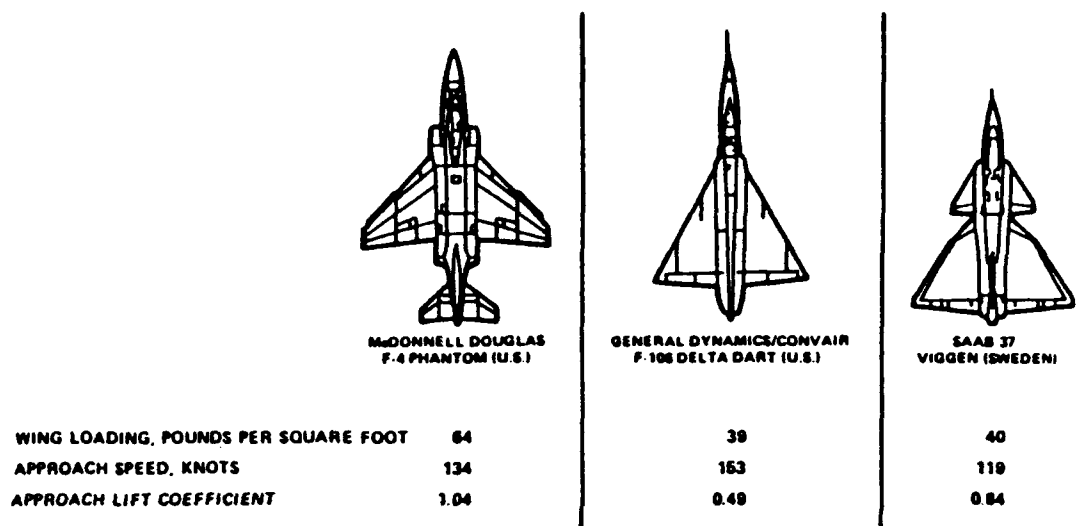

Extensive research has been performed related to the phenomenon of canard/wing interaction [Ref. 2,3,6,7]. These experimental results indicate two possible mechanisms by

which the flowfield from the canard affects the flowfield around a wing. One is the impingement of the canard downwash on the apex of the main wing; the other is the favorable interference between the canard and wing leading-edge vortices. For low angles of attack, the canard produces a downwash field within its span and an upwash field outside its span. The result is a nonuniform angle of attack on the main wing. The inner (inboard of the canard span) and forward portions of the wing have a lower effective angle of attack than the outer and rear portions. The flow over the wing behind the canard tends to remain attached while the flow outside the canard or at the rear of the wing tends to separate. The probable result is an overall loss of lift on the main wing which has to be compensated for by the increased lift of the canard. In fact, studies such as Reference 6 show that at low angles of attack ( $<10^\circ$ ) the lift-curve slope of a model with or without a canard is identical. The second mechanism occurs at higher angles of attack. As the angle of attack is increased, a strong leading-edge vortex is formed on the canard. As this vortex moves over the wing it acts to energize the wing leading-edge vortex, thereby delaying Vortex-Breakdown (VBD). [Ref. 3,7]

### **1. Canard Versus Tail**

The first advantage of the canard over the horizontal tail design arises from a difference in trim requirements. A conventional tail balances an aircraft in flight by producing a downward lift vector. This results in an initial decrease in lift for a trim to lower speed. A canard, on the other hand, produces a large nose-up pitching moment which must be balanced by a positive elevon deflection on the main wing. The result is increased lift for the canard aircraft due simply to the difference in the trim requirements. This effect is most dramatic when comparing a pure delta-wing aircraft with a canard/delta-wing combination. Figure 3 shows the wing loading, approach speed and lift coefficient for three high-performance aircraft. The Viggen has approximately the same wing loading

as the F-106, but the Viggen approach speed is 34 knots slower than that of the F-106 with a 70% higher lift coefficient.[Ref. 2]

**Figure 3. Characteristics of the F-4,F-106 and Viggen [Ref. 2]**

Additionally, the increased lift of a canard-configured aircraft cannot be completely accounted for simply by the increased lifting area of the canard. Work done by Er-El [Ref. 3] showed an increase in normal-force coefficient of 18% at  $22^\circ$  angle of attack, over that of a corresponding wing-alone configuration. The canard itself added only 9% to the total lifting area. Likewise, extensive work done by Lacey [Ref. 2] showed similar results. Figure 4(a) shows that the stall of a wing alone and of a wing/conventional-tail combination occurs at about  $21^\circ$ , whereas there is no indication of stall for the canard-configured aircraft below  $32^\circ$ . Additionally, for low values of  $C_L$  drag of the all three configurations was the same, see Figure 4(b). Therefore, during cruise flight the canard/wing configuration would

configuration. Again, the increase in lift of the canard/wing configuration at high angles of attack could not be completely accounted for by the additional lifting area of the canard.

Figure 4a. Lift Coefficient due to a Canard and Horizontal Tail [Ref. 2]

Figure 4b. Drag Polar for a Canard and Horizontal Tail [Ref. 2]

### C. VORTEX INTERACTION

Er-El [Ref. 3] conducted an investigation of vortex trajectory and breakdown using canard/wing configurations at angles of attacks between  $13^\circ$  and  $30^\circ$ . Er-El states that near the wing apex, the downwash of the canard forces the wing vortex down closer to the wing, while further downstream the vortex trajectory is more influenced by the canard leading-edge vortex than by its downwash. That is, near the trailing edge, the wing vortex

is displaced upward and outward, away from the adverse pressure gradient. Er-El also states that a close-coupled canard causes a delay in the onset of the breakdown of the wing leading-edge vortex, which originates at the wing apex. This delay is possibly a result of the wing vortex movement away from the adverse pressure gradient, thereby making it more stable.

#### **D. PREVIOUS TESTING**

At the Naval Postgraduate School, Kersh performed force measurements on a model designed in accordance with Lacey's guidelines. [Ref. 6] Kersh investigated the effects of canard-enhanced lift at five angles of attack between  $10^\circ$  and  $48^\circ$ . Figure 5 [Ref. 6] is the lift curve that resulted from that study. Note that as mentioned earlier the point of maximum lift enhancement occurred at  $22^\circ$ , the point of first stall for the wing/body configuration. At  $22^\circ$  there was a 34% increase in lift for the canard/wing configuration over that for the wing/body configuration. In addition, surface flow visualization indicated the dramatic effect the canard vortex had on the main wing flowfield. However, while the flow visualization gave outstanding insight into the nature of the flow on the surface of the wing, it did not say much about what occurred off the wing surface. That flowfield study was the major objective of this study.

Figure 5. Lift Coefficient of Wing/body and Maximum Lift of Canard/Wing  
[Ref. 6]

### III. EXPERIMENT AND PROCEDURES

#### A. PURPOSE

This study was conducted to investigate the effects of vortex interference on the flowfield around the main wing of a close-coupled canard and wing combination. A nulling five-hole pressure probe was used to make flowfield pressure measurements in the three crossplanar grid locations shown in Figure 6. These pressure measurements were then used to determine local flow velocities, pressures, and pitch and yaw angles for use in mapping the position and interaction of canard and wing vortices.

Figure 6. Model Overview

## B. APPARATUS

The primary equipment used in this study were a wind tunnel, a close-coupled canard model, a three-dimensional traversing mechanism, a rotary pressure transducer, a data acquisition system, and a nulling five-hole pressure probe.

### 1. Wind Tunnel

The tunnel was of the close-circuit, single-return type. It measured 64 feet in length and between 21.5 and 25.5 feet in width with a test section cross-sectional area of 8.75 square feet. The tunnel was powered by a 100hp electric motor coupled to a three-bladed variable pitch fan via a four-speed transmission. Figure 7 is a schematic of the tunnel.

Figure 7. Naval Postgraduate School Wind Tunnel [Ref. 8]

Tunnel turbulence was minimized by the use of stator blades, turning vanes and turbulence screens. Eight stator blades were used to remove swirl imparted to the flow by the fan blades. Turning vanes were located at each corner to turn the flow while maintaining its kinetic energy and turbulence screens were placed in the settling chamber.

The test section measured 45 inches by 28.5 inches with a cross-sectional area about one tenth that of the settling chamber. The test section was rectangular with slightly divergent walls to account for boundary layer growth. Breather slots at the far end of the test section were used to keep the test section at approximately atmospheric pressure. Due to the configuration of the pressure measuring equipment, ambient atmospheric pressure was used as the reference static pressure rather than test section static pressure. [Ref. 8]

Tunnel velocity was set by reference to a water manometer that measured the difference in static pressure between the settling chamber and the test section. The static pressures in the settling chamber and at the test section entrance were determined by reference to four pressure ports, one on each wall. The pressures from these ports were averaged by a common manifold prior to the manometer. The manometer measured the pressure difference in centimeters of water and the test section velocity was then determined by equation (1).

$$V = \{(2 \cdot 2.0475 \cdot P_{\text{cmH}_2\text{O}}) / (\rho \cdot K)\}^{1/2} \quad (1)$$

where:

V	Test Section Velocity (ft/sec)
2.0475	Converts From Centimeters of Water to Lbf / ft <sup>2</sup>
P <sub>cmH<sub>2</sub>O</sub>	Manometer Reading (cm of water)
ρ	Density of Air (slugs/ft <sup>3</sup> )
K	Tunnel Calibration Factor (P <sub>cmH<sub>2</sub>O</sub> /q)

The tunnel calibration factor, the ratio of the static-pressure ratio to the test section dynamic pressure, was determined to be 0.925.

## **2. Model Design**

The model used in this study was originally used by Kersh [Ref. 6] and was designed in accordance with the earlier work of Lacey [Ref. 2]. During Lacey's studies, a canard-area-to-wing-area ratio of 0.20 as referenced to the model centerline of the fuselage was used. Because it was desired to accommodate an internal mechanism for a movable canard, the fuselage of this model was larger than that of Lacey's model. Therefore, this model was designed with an exposed canard-area-to-wing-area (wing referenced to the centerline of the fuselage) ratio of 0.20. If the area ratio had not been determined this way, a canard exposed area much smaller than Lacey's would have resulted. If the area ratio of Lacey's model had been determined by this same method, a ratio of 0.13 would have resulted. Consequently, an exposed canard-area-to-wing-area ratio of 0.20 compared favorably with that of Lacey's model.

Lacey's work also showed that the relative position of the canard to the wing was crucial for constructive canard/wing interference. According to Reference 2, the longitudinal position of the canard ( $X$ ), non-dimensionalized by the mean aerodynamic chord (MAC) of the wing referenced to the fuselage centerline ( $X/C_{mac}$ ), should not be greater than  $X/C_{mac}=1.5$ . The longitudinal distance was measured from the 40% chord location of the exposed canard root to the quarter chord of the wing MAC. Also, there should be no overlap of the main wing and canard. As a result, the canard was positioned at  $X/C_{mac}=1.2$ . The canard vertical position was  $Z/C_{mac}=0.2$ ; which was chosen such that it would match Lacey's model.

The wing and canard were both an NACA 64A008 airfoil section, which was the same section used by Lacey. The canard had a leading-edge sweep of  $60^\circ$ , a straight-taper of 0.1 and an aspect ratio of 2.0. The wing had a leading-edge sweep of  $50^\circ$ , a straight-

taper of 0.15 and an aspect ratio of 3.0. These planforms were chosen to ensure that strong leading-edge vortices would be generated. Unlike the sharp leading-edge model used in Er-El's studies [Ref. 3], both the canard and wing had rounded leading edges. No attempt was made to trip the boundary layer. Planform geometry was derived from equations (2), (3) and (4). [Ref. 6]

$$AR = 2\{b/C_R(1+\lambda)\} \quad (2)$$

$$AR = b^2/S \quad (3)$$

$$MAC = 2/3\{C_R + C_t - [C_R C_t / (C_R + C_t)]\} \quad (4)$$

Where:

AR	Aspect Ratio
b	Span
C <sub>R</sub>	Length of Root Chord
C <sub>t</sub>	Length of Tip Chord
λ	Taper Ratio (C <sub>t</sub> /C <sub>R</sub> )
S	Area of Wing or Canard
MAC	Wing Mean Aerodynamic Chord

Figure 8 is a schematic of the model and contains a listing of its geometric data. Reference 6 contains a thorough description of the model's design. Because the five-hole pressure probe was not long enough to reach the model mounted on the tunnel floor, a platform was constructed to elevate the model (see Figure 9). The effect on the flowfield should be minimal for the half-model, as the raised platform acted in a similar manner to the reflection plane.

**Figure 9(a). Side View of the Model Mounted in the Tunnel**

**Figure 9(b). Front View of the Model Mounted in the Tunnel**

### **3. Velmex 8300 Three-Dimensional Traverser System**

The Velmex system, shown in Figure 10, was used to accurately position the five-hole pressure probe in the test section. The system consisted of the traverser mechanism, Figure 10(b), and the motor controller, Figure 10(a). The traverser mechanism was composed of leadscrews, slides and motor/jackscrew assemblies. Each motor was a 200-step-per-revolution, 10-amp stepping motor with a maximum velocity of 3000 steps per second. The motor step size was 1/200 of a revolution which equated to 0.000125 inch. The three motor assemblies received their commands from the controller which was capable of interpreting signals from either a parent computer or manual inputs at the controller. During this study the controller received its commands from a parent PC/AT.[Ref. 9]

### **4. Rotary Pressure Transducer and Data Acquisition System**

A 48-port rotary pressure transducer (commonly referred to as a Scanivalve®) read each port of the pressure probe twice per measurement point. The data acquisition system, shown in Figure 11, consisted of the required hardware and software to allow a PC/AT to acquire the pressure data. The Scanivalve® put out a 7-bit binary coded decimal signal that corresponded to the port currently being monitored. This arrangement allowed remote, electronic monitoring and control of the Scanivalve® assembly. [Ref. 10] After the pressure signal, in the form of an analog voltage, left the Scanivalve® it was passed to the Relay Multiplexer, then to the Digital Multimeter (DMM). The DMM converted the analog voltage signals to a digital form which were then sent to the computer for further processing.

### 5. Five-Hole Pressure Probe

The three-dimensional five-hole pressure probe, shown in Figure 12, was made of corrosion-resistant, non-magnetic, stainless steel. It was 0.125 inches in diameter and 24 inches in total length. At the tip of the probe were five measuring holes. The center hole of the probe ( $P_1$ ) measured total pressure, the two lateral holes ( $P_2, P_3$ ) were used to measure yaw angle and static pressure, and the top and bottom holes ( $P_4, P_5$ ) were used for pitch information. [Ref. 11]

**Figure 12. The Five-Hole Pressure Probe [Ref. 11]**

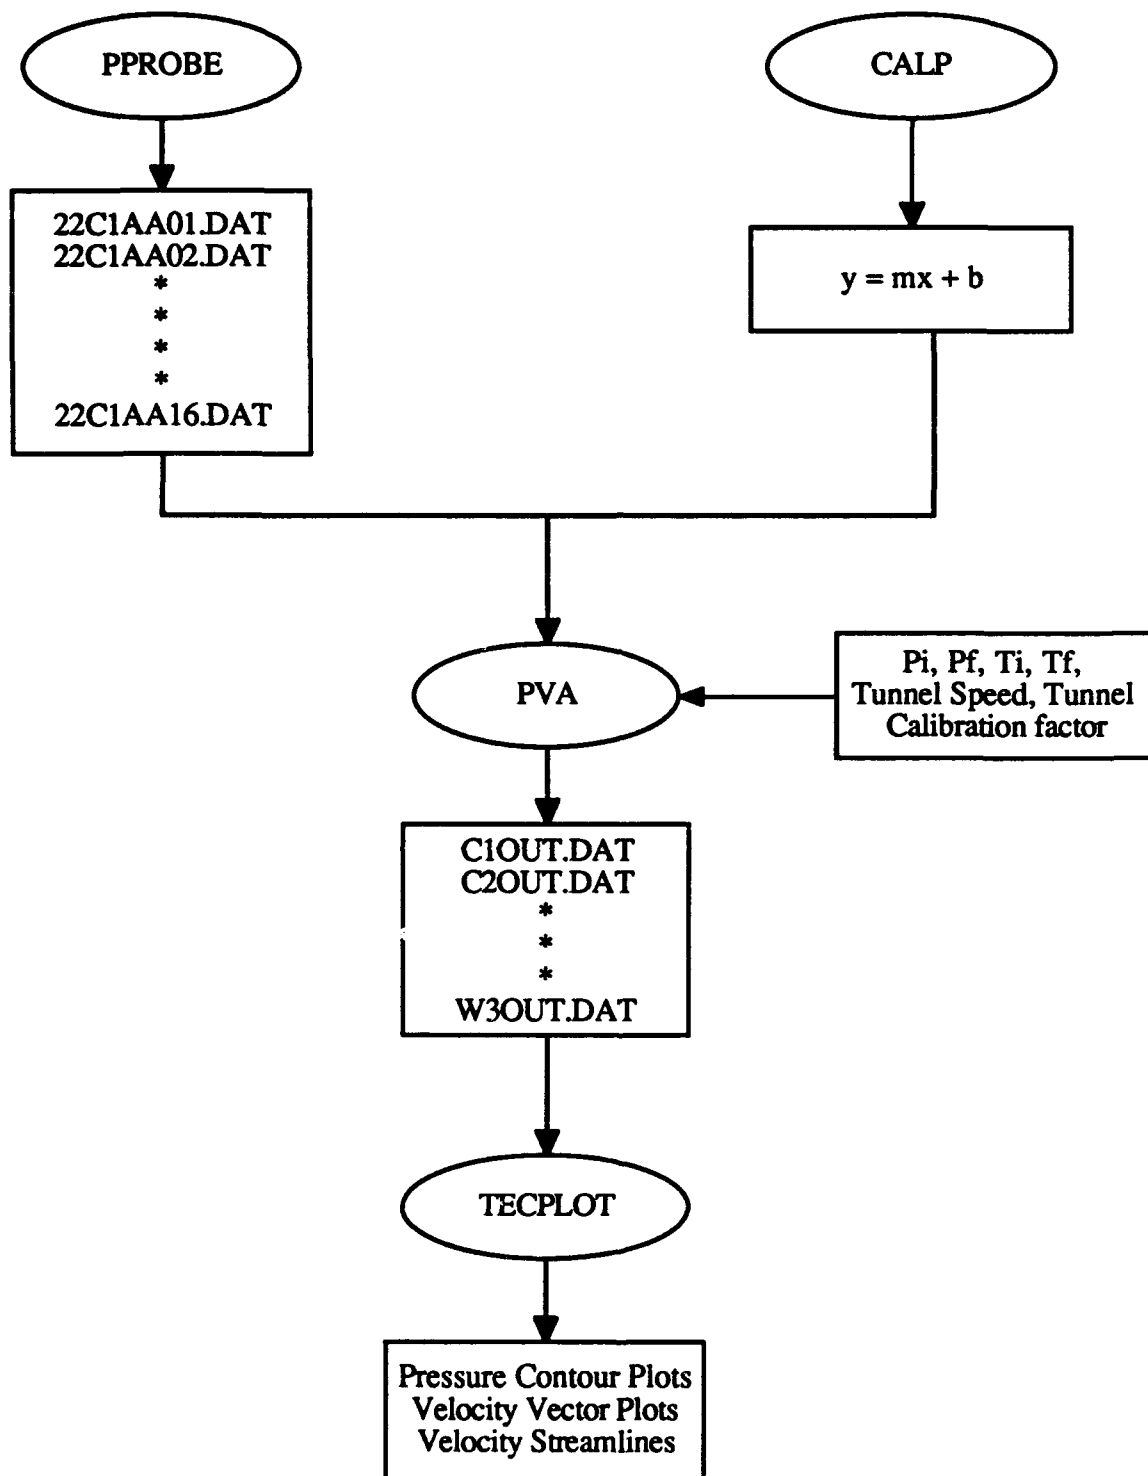

## **C. EXPERIMENT SOFTWARE**

The software used in this study was developed by Lung during his work with the five-hole pressure probe [Ref. 10]. Some modifications were made to accommodate this work, but the flow of data remained essentially the same. Figure 13 is a schematic flowchart of the various programs and data files. The following sections discuss the individual programs.

### **1. PPROBE**

PPROBE (Appendix A), written in BASICA by Kindelspire [Ref. 12], and modified by Lung [Ref. 10], was used to control the data acquisition process. Figure 14 is the program flow chart for PPROBE. The two primary responsibilities of PPROBE were the control of the traverser and the recording of the data.

First, PPROBE was used to manually position the probe to the proper starting point in the tunnel, then the dimensions of the grid to be measured and the desired step size were entered. PPROBE calculated the total number of points to be measured, created the required number of data files and initialized the data acquisition equipment. The operator then physically nulled the probe and entered the observed yaw angle into PPROBE. PPROBE rotated the pressure transducer to the appropriate port and began measuring the analog voltage which corresponded to the pressure at that port. Finally, the data were displayed to the operator and he was given a chance to remeasure the data point. If the data were acceptable PPROBE moved the traverser to the next measuring point. At the completion of each column in the grid, the data were placed into a file to be used in the program PVA.

**Figure 13. Data Flow Path**

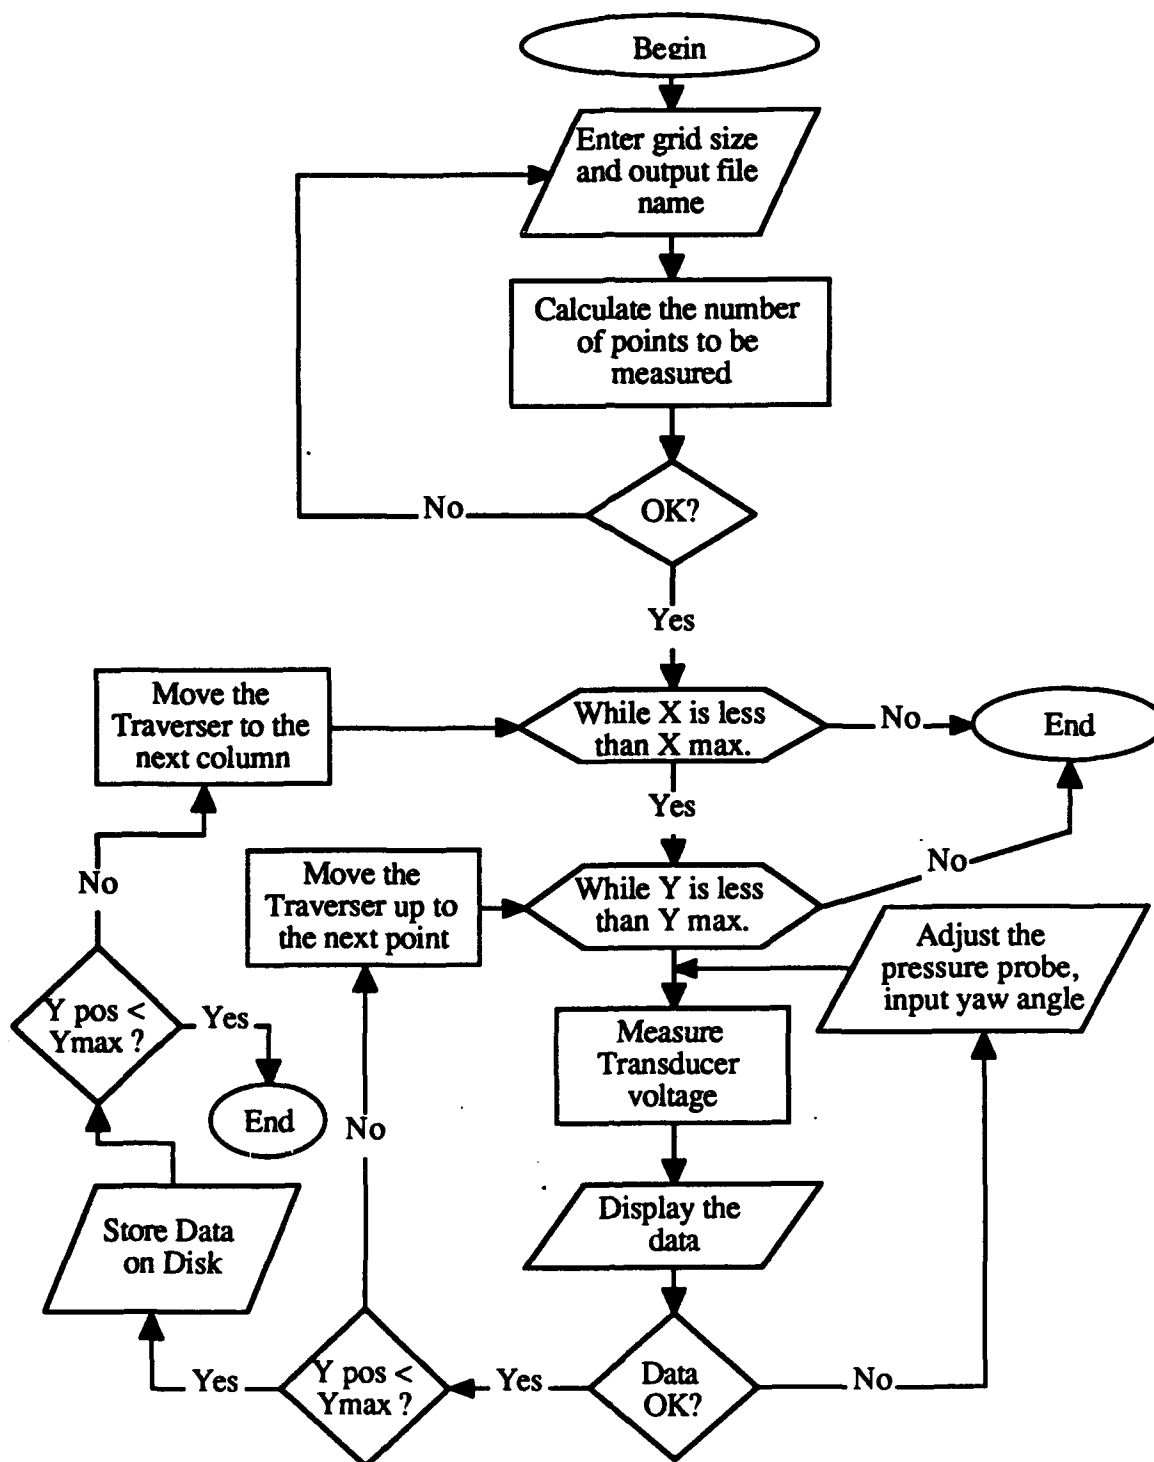

Figure 14. PPROBE Flow Chart

## 2. CALP

CALP (Appendix B), was written in BASICA and used to calibrate the pressure transducer prior to each data collection period. The calibration manometer is shown in Figure 15. Six pressures were recorded using the calibration manometer and the pressure transducer in the Scanivalve<sup>®</sup> to provide a known calibration curve for the experiment. A straight line was fit to the data, whose slope and intercept were input to the PVA program.

Figure 15. Calibration Manometer

### 3. PVA (Pressure Velocity Angle)

PVA (Appendix C) was a modified version of CONVERT, a Fortran program which combined the output of PPROBE and CALP to calculate the flowfield properties [Ref 10]. PVA used the pressure data, in the form of analog voltages, and yaw data from PPROBE, and combined them with the curve fit derived from the CALP output to determine the desired flowfield characteristics. See Figure 16 for the PVA flow chart.

Specifically, PVA determined:

- freestream velocity (V)
- crossflow components of freestream velocity ( $V_x$  and  $V_y$ )
- total pressure and total pressure coefficients
- static pressure and static pressure coefficients
- flow yaw and pitch angles

The pressure coefficients were determined as follows:

$$C_{PT} = (P_{T1} - P_{amb} - Q_1) / Q_1 \quad (5)$$

$$C_{ps} = (P_{s1} - P_{amb}) / Q_1 \quad (6)$$

Where:

$P_{T1}$  = Local Dynamic Pressure

$P_{s1}$  = Local Static Pressure

$P_{amb}$  = Room Ambient Pressure

$Q_1$  = Freestream (Tunnel) Dynamic Pressure

Due to the configuration of the pressure-measuring equipment, room ambient pressure was used as the reference static pressure in the pressure coefficient calculations. The output of PVA was put in an ASCII file for use by commercially available graphic software for plotting the desired output.

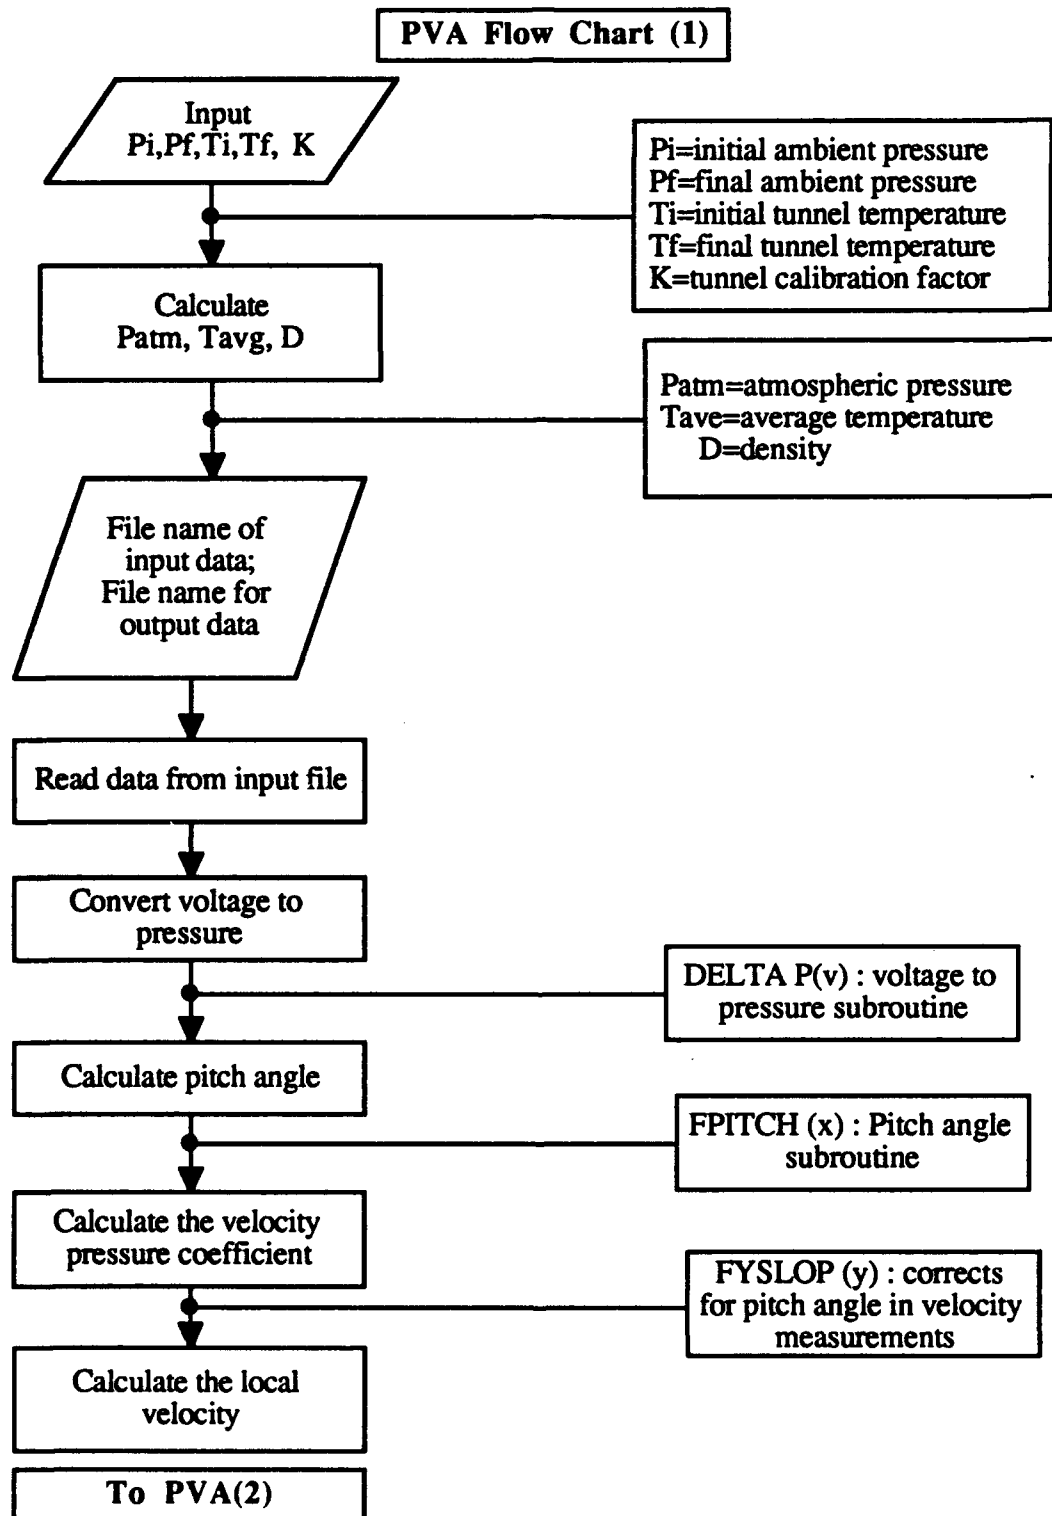

Figure 16(a). PVA Program Flow Chart

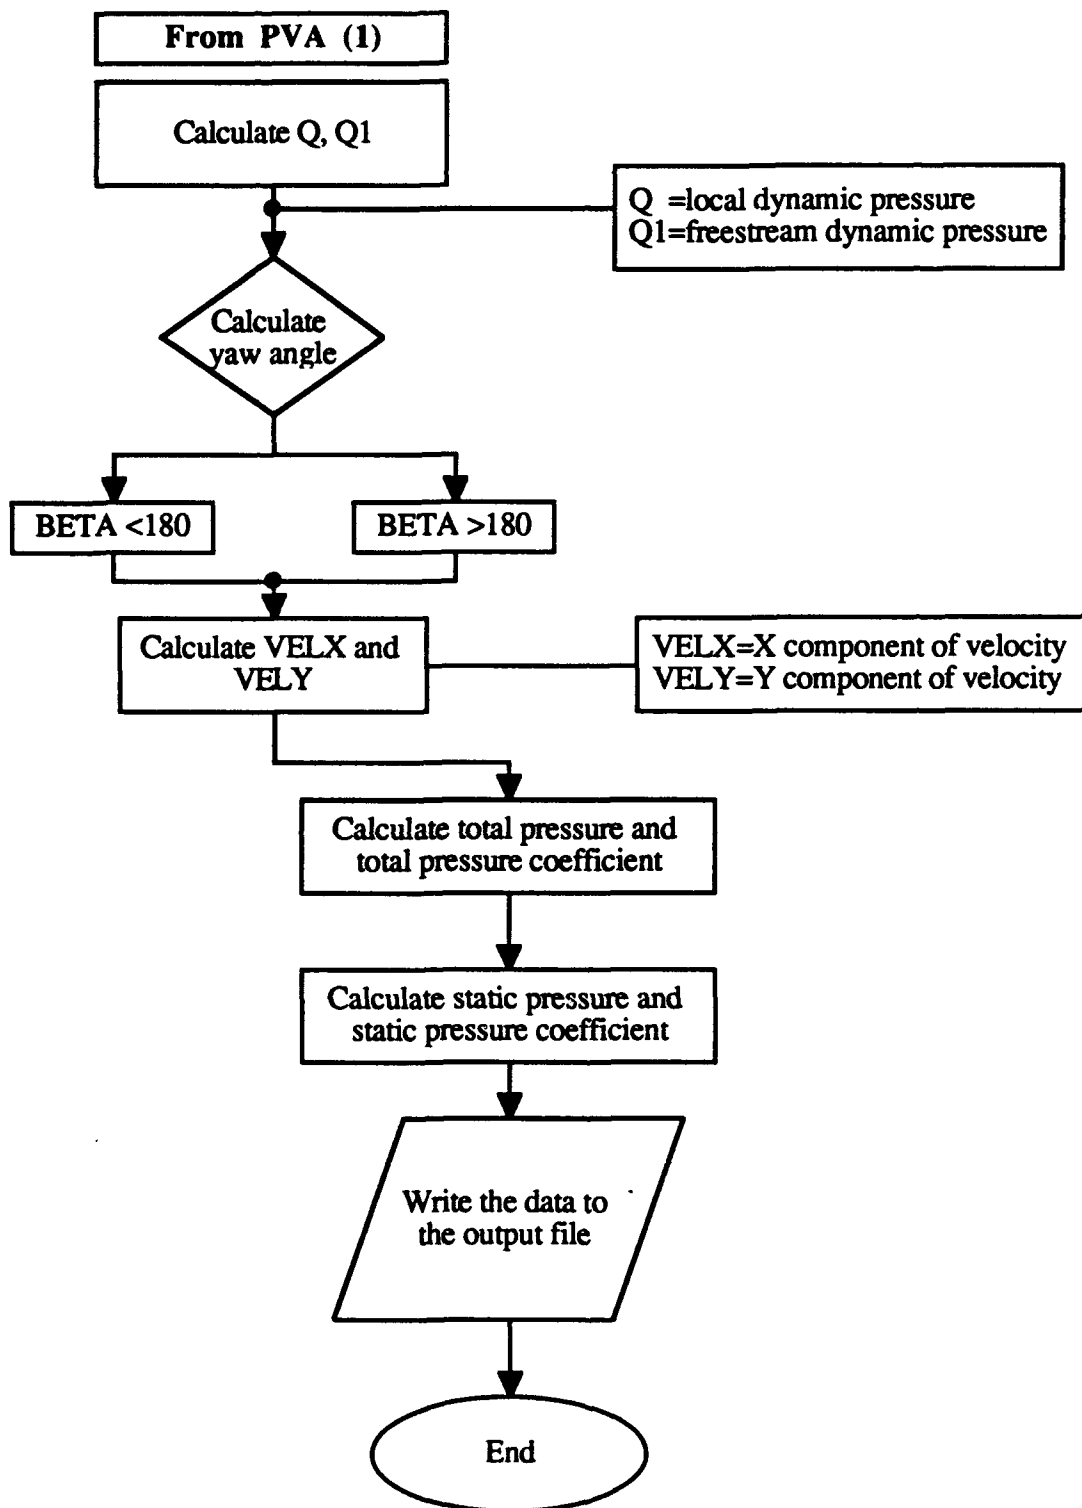

Figure 16(b). PVA Program Flow Chart

#### **D. EXPERIMENTAL CONDITIONS AND PROCEDURES**

To correlate these results with the results of Kersh, the experimental conditions were kept as constant as possible. A reference measured pressure difference of 17 cm of H<sub>2</sub>O was set, resulting in a test-section dynamic pressure of 37.63 lbf/ft<sup>2</sup> and an average velocity of 177 ft/s. The Reynolds number was  $Re=9.5 \times 10^5$  based on the main wing mean aerodynamic chord.

To account for possible tunnel crossflow, probe installation effects and flowfield disturbances caused by the model platform, an initial run was made without the model installed, to establish baseline yaw and pitch values. This measurement was again run at the end of testing to ensure the baseline values had not changed appreciably.

Measurements were made at three locations, numbered as shown in Figure 6. Grids 1 and 2 were mapped at 1/4" intervals, while grid 3 was mapped at 1/2" intervals. Note that the measuring plane of the grids were perpendicular to the freestream direction, rather than to the wing chord.

Grid 1 was 4" by 5" and was set just behind the canard trailing edge in order to capture the canard leading-edge vortex. Grid number 2 was 5.5" by 6" and was placed at the mid-point of the wing to capture the effect of the canard leading-edge vortex on the flowfield at that point. Finally, since flow visualization, completed earlier, had shown the flowfield beginning to lose its coherency near the trailing edge of the wing, grid number 3 was placed just behind the trailing edge of the wing. Grid 3 measured 7.5" by 6"; because its size would have necessitated an excessive amount of tunnel time to complete at 1/4" intervals, it was mapped at 1/2" intervals.

#### IV. RESULTS

The following sections discuss the results of this study. In each section there will be three plots. The first will be a plot of flowfield velocity vectors, then a plot of the velocity streamlines, followed finally by a plot of total-pressure-coefficient contours. Flow visualization results are also included to correlate with the measured data. All the plots are scaled in inches, with "X" plotted horizontally, transversely to the tunnel and "Y" plotted vertically to the tunnel. Locations on the plots will be identified by listing the coordinates in the standard (X,Y) convention. Also, the plotted data are shown with cutaway views of the model geometry to establish the relative position of the measuring plane to the model. At grid 1 the actual measuring plane was just beyond the canard trailing edge, but the canard cross-section at the trailing edge will be shown for reference. Likewise, at station three the grid was located after the main wing trailing edge, but the wing cross section 3 is shown to indicate the relative position of the vortices and main wing (see Figure 17).

Figure 17. Model Side view

Because of the dynamic nature of flowfields surrounding aerodynamic surfaces at high angles of attack, there were regions in which the capabilities of the probe were exceeded. In particular, the probe was unable to make accurate measurements downstream of stalled aerodynamic surfaces or near the core of a vortex. Precisely, in these regions the probe could not be nulled - that is,  $P_2$  and  $P_3$  could not be made equal. The main effect of this probe limitation was that the exact positions of the vortex cores could not be determined. During data reduction, to account for the regions of the flowfield where the probe could not be nulled, a value of zero velocity was assigned and a limiting value of total pressure drop was established based on observed trends in the area of the flowfield where accurate data were available. Therefore, the velocity vector plots and velocity streamline plots have areas where there are no data present; these areas are the sections of the flowfield where the probe capabilities were exceeded. Likewise, on the pressure contour plots an area of uniform total pressure loss indicates the section in which the data are inaccurate. The isobar along which the pressure data become unreliable will be delineated in the section which refers to that plot.

An additional problem of the probe's lack of capabilities arises from the fact that both vortical flow and the reversed flow from a stalled aerodynamic surface appear as blank areas in the data or as areas of total pressure loss. Since there is insufficient data to indicate a difference between the two flow states, flow visualization results have been included to discern between regions of separated/reversed flow and those of separated coherent vortex flow.

#### **A. WING-ALONE**

With the canard off, the flow over the main wing was characterized by large regions of reversed flow, indicative of a stalled wing. In general, as can be seen from Figure 18, there was a large amount of oil over the majority of the wing indicating wing stall. Particularly,

the oil on the inboard portion of the wing was mostly stagnate or flowing spanwise; this response indicated that this section of the wing had stalled and thereby created an area of large total pressure loss. Along the leading edge of the wing there appeared to be a weak, poorly organized, separated vortex, which apparently lost its coherency over the outboard section. This separated vortex was indicated in Figure 18 by the heavy line of oil which started at the wing apex and then seemingly burst at the wing mid-point. Therefore, it would be expected that at each measuring grid there would be evident a general tendency for the flow to move spanwise, in a root-to-tip fashion, with a large area of total pressure loss. In this case, the loss in total pressure would be due to chaotic, disorganized, separated reversed flow rather than coherent, vortical flow.

Figure 18. Wing Alone Set at 22°

### **1. Mid-Point of the Main Wing (Grid 2)**

Figure 19(a) is a plot of the "X" and "Y" components of the local velocities at grid 2. The blank area inside the heavy line indicates the area where the data were unreliable due to flow separation. The crossflow component of freestream velocity increased as the probe was traversed from the wing tip to the root. The crossplane velocity streamline plot of Figure 19(b) shows a vortical pattern which compares favorably with the flow visualization of Figure 18. Crossplane velocities are vertical (in the model reference sense) near the leading edge or tip, but horizontal at 26% mean aerodynamic chord (MAC) above the wing. Figure 20 is a contour plot of total-pressure-coefficient loss. This plot also shows an area of total pressure loss increasing in size as the probe was moved inboard toward the wing root. At the outboard section of the wing it is possible that the cause of this loss was the disintegrating vortex that appeared to form there; however, at the inboard section, the loss was certainly caused by reversed flow. Pressures inside the -1.24 isobar are unreliable. The separated region extends up to 29% MAC.

### **2. Trailing Edge of the Main Wing (Grid 3)**

At grid 3, which was located just past the trailing edge of the wing, Figures 21(a) and (b) clearly indicated a strong spanwise flow pattern from the wing root to the tip near the fuselage. This flow pattern is believed to be caused by entrainment due to the separated reversed flow commonly associated with wing stall, rather than by a coherent vortex. The separation now extends about 57% of the MAC above the wing plane at the trailing edge. The total-pressure-coefficient gradients in Figure 22 show that the region of total pressure loss, due to the stalled reversed flow, had grown substantially as the flow moved downstream from grid 2. Pressures inside the -1.20 isobar are considered to be unreliable. Though the region of uncertain data is large, the results seem to indicate the extent to which the flow separation affects the wing flowfield, just as the oil flow visualization seemed to indicate the same on the wing surface.

Figure 21(b). Streamlines, Trailing-Edge of the Wing, No Canard

Figure 22. Total Pressure Coefficient Contours, Trailing-Edge of the Wing, No Canard

## B. WING/CANARD COMBINATION

The addition of the canard to the model caused large-scale reattachment of the flow over the wing. Figure 23 shows a well-defined secondary separation line along the leading edges of both the canard and wing. These separation lines are characteristic of strong, highly coherent leading-edge vortices. Note in Figure 23 that despite the high angle of attack of the canard ( $29^\circ$ ), the flow appeared to remain completely attached (not separated and reversed) and that the large leading-edge sweep ( $60^\circ$ ) produced a strong vortex even though the leading edge was rounded. In reference to Figure 23, the wing can be seen to be fairly clean of oil with the exception of a wedge which started just aft of the apex and grew as it proceeded downstream parallel to the fuselage. Also, there is a line of oil along the trailing edge of the wing which indicated that the flow had begun to separate there, particularly at the point where the trailing-edge line joined the line which had started near the apex and moved parallel to the fuselage. Additionally, looking at the top surface of the fuselage where the canard and wing join the body, one can see there is a section of the fuselage free of oil. It is thought that this result was due to a secondary vortex forming near the surface of the fuselage. The exact origin of this secondary fuselage vortex, however, is not clear. It could have been the result of either the forebody or of the leading-edge vortices formed on the canard and wing, or possibly some combination of the two effects.

The discussions that follow will be in the same format used in the preceding wing-alone discussion. The path of the canard and wing vortices will be analyzed and the effects of the one on the other noted.

**Figure 23. Model set at  $22^\circ$ , Canard set at  $7^\circ$  Incidence**

### **1. Trailing Edge of the Canard (Grid 1)**

The flow at this grid, which was located just aft of the canard trailing edge, was dominated by a strong vortex generated at the canard leading edge. Figure 24(a) shows that for a large portion of the measuring grid, the probe was unable to accurately record flow field pressures. However, Figures 24(a) and (b) do indicate the presence of very strong vortical flow in a clockwise direction. Also, Figures 24(a) and (b) indicate the presence of a secondary vortex forming toward the fuselage surface near the canard/body juncture. The secondary vortex was rotating in a counter-clockwise direction, which indicated that it had probably formed as a result of the canard leading-edge vortex in much the same manner as

a secondary vortex forms near a wing leading-edge vortex. The mechanism for such a vortex would be the same as that depicted in Figure 1, but would be a result of an interaction of the wing and fuselage rather than the wing and itself. Such a phenomenon had not been noted in previous testing because the models used did not have a substantial fuselage. If this secondary vortex had resulted from the model forebody, it would have been expected to be rotating clockwise.

Figure 25 shows the steep pressure gradients which resulted from this vortex. The data inside the -1.26 isobar are unreliable, but clearly, the trend was for a tight, coherent core vortex standing approximately 1.5 to 2.5 inches off the canard surface at the trailing edge. The presence of the secondary vortex near the canard root is better indicated in the plot of total-pressure-coefficient-loss contours. Notice that a freestream value of total pressure extends all the way to the canard surface, which agrees with the flow visualization of Figure 23.

Figure 24(a). Velocity Vectors, Trailing-Edge of the Canard

Figure 24(b). Streamlines, Trailing-Edge of the Canard

Figure 25. Total Pressure Coefficient Contours, Trailing-Edge of the Canard

## **2. Mid-Point of the Main Wing (Grid 2)**

A comparison of Figures 26 and 19 shows a dramatic difference in the flowfield due to the addition of the canard to the model. Figure 26(a) shows two regions of unobtainable data, one at approximately (5,2) and the other very near the wing leading edge at about (0.5,3.5). The area located near (5,2) was the canard leading-edge vortex which had moved downstream from grid 1. The area near (0.5,3.5) could have been the result of two possible phenomena. One is that the large region of chaotic flow seen in Figure 19 had been forced into a small "pocket" of separated reversed flow. The second is that the wing leading-edge vortex had reformed due to the presence of the canard vortex. The flow visualization in Figure 27 indicates the presence of a wing leading-edge vortex. Furthermore, the pattern formed by the streamlines in Figure 26(b) indicates that rather than the flow having merely been forced into a "separation-pocket", the leading-edge vortex was actually energized by the canard vortex and had reformed. The flow visualization suggests that a strong vortex has formed along the wing surface.

The energizing of the wing leading-edge vortex in this manner and the reattached flow over the inboard wing section would lead to a level of enhanced lift which would be greater than that obtained by simply adding the lifting surface of the canard. In fact, as was mentioned earlier, this was found to be exactly the case in previous studies [Ref. 2,3]. The mechanism is clearly demonstrated here. Also in Figure 26 can be seen a significant crossflow component between the canard vortex and the wing leading-edge vortex. In the vicinity of (2,1) the crossflow is as much as 65% of the total freestream velocity and approaches the wing perpendicular to its surface. The formation of oil parallel to the fuselage in Figure 27 could have been due, at least in part, to the stagnation of this large crossflow component on the wing surface.

The total-pressure-coefficient contours of Figure 28 show the presence of a third vortex not completely captured by the velocity-vector or velocity-streamline plots. Centered

at (2.1,0.6), this vortex is believed to be the secondary vortex that had formed on the fuselage surface at grid 1. Most importantly, the contours of Figure 28 show that freestream total pressure extended to the wing surface over the inboard section. Clear evidence is provided that the flow had reattached over the inboard portion of the wing, enhancing significantly the lifting ability of the previously stalled wing.

Figure 27. Wing at  $22^\circ$  with Canard Deflected  $7^\circ$

Figure 28. Total Pressure Coefficient Contours, Mid-point of Wing, With Canard

### 3. Trailing Edge of the Main Wing (Grid 3)

While the velocity vectors and streamlines of Figure 29 indicate a similar pattern to that of grid 2, the flow, in general, was less coherent and slightly more diffuse than at grid 2.

Figure 29(a) shows that there were two areas devoid of obtainable data. One of these areas was the result of the canard vortex which had moved downstream to a point near the (5.5,1.5) position and the other was caused by the wing leading-edge vortex which had reformed as a result of the presence of the canard. The streamlines in Figure 29(b) show that the flow at these locations was strongly vortical. In addition, the flow visualization of Figure 27 shows the presence of a secondary separation line consistent with the formation of a leading-edge vortex. Figure 29 also indicated that there still existed a strong crossflow component moving from the canard vortex to the wing vortex. The magnitude of this crossflow reached 66% of the freestream as at grid 2; however, the freestream velocity on the wing surface of grid 3, near (0,2.5), had slowed to 74% of that at the same position on grid 2. This was substantiated by the growth in the width of the oil line parallel to the fuselage. A comparison of Figures 18 and 21 with 29 shows that the energy introduced to the flow by the canard vortex moved the burst point of the wing leading-edge vortex past the trailing edge of the wing.

The pressure contours in Figure 30 show the presence of the two vortices already mentioned and a third area of pressure loss. This third area was most likely a combination of the remnants of the secondary fuselage vortex and the stagnation of the spanwise crossflow component on the wing. Note also that even though the canard vortex had traveled the length of the model, the pressure gradient around it was approximately equal to that around the wing leading-edge vortex. This further indicates that it was the energy in the canard vortex which allowed or entrained the wing vortex to reform. The -1.21 isobar marks the limit of the probe capabilities.

Figure 30. Total Pressure Coefficient Contours, Trailing-Edge of the Wing, With Canard

### C. CONCLUSION

The addition of the canard had a dramatic effect on the wing flowfield at an angle of attack of  $22^\circ$ . Without the canard, the flow across the wing was characterized by large areas of chaotic, incoherent flow with a resultant loss in lift. The addition of the canard vortex established a large crossflow component moving toward the wing surface which caused the flow over the inboard section of the wing to reattach.

In addition to reattachment, the crossflow provided energy to the wing vortex which delayed its breakdown. Therefore, with the canard in this position relative to the wing, the wing leading-edge vortex was enhanced and stabilized. This crossflow-induced breakdown delay substantiates the conclusions made by Lacey, in Reference 2.

The energy contained in the canard vortex is not lost. Consider the drag force as a measure of the energy required to propel two models with the same wing planform. The first model employs a canard/wing configuration and the second model a wing/conventional-tail configuration. If the flow over the wing of the second model remains attached (this study shows it would not), both models would have approximately the same drag. The difference is that the energy (in the form of drag) placed in the tail vortex of the second model would be lost to the freestream. In the canard/wing configuration, some of the energy placed in the canard vortex was used to benefit the flow over the wing thereby, making the canard configuration more efficient.

Figure 31 is provided as a schematic of the approximate path of the vortices as they moved downstream through the grids.
